
Making Tools and Making Sense: Complex, Intentional Behaviour in Human Evolution

Dietrich Stout & Thierry Chaminade

Stone tool-making is an ancient and prototypically human skill characterized by multiple levels of intentional organization. In a formal sense, it displays surprising similarities to the multi-level organization of human language. Recent functional brain imaging studies of stone tool-making similarly demonstrate overlap with neural circuits involved in language processing. These observations are consistent with the hypothesis that language and tool-making share key requirements for the construction of hierarchically structured action sequences and evolved together in a mutually reinforcing way.

Although it may appear esoteric in the modern world, stone tool-making has been practised in one form or another by virtually every human society for the past 2.5 million years. 2.6-million-year-old stone artefacts from Ethiopia (Semaw *et al.* 1997; 2003) provide the earliest evidence of uniquely hominin tool-making capabilities and exemplify a basic human technology that remained widespread until the recent past, and in some cases endured into the modern era (Roux *et al.* 1995; Skerchly 1984; Stout 2002; Weedman 2000). In fact, stone tool-making is a prototypical human skill integrating demands for planning, problem-solving and perceptual-motor coordination within a pragmatic, collaborative context. Together with its likely evolutionary importance, this makes stone tool-making an important object of study for cognitive neuroscience as well as archaeology.

The Early Stone Age (ESA) alone encompasses roughly 90 per cent (2.6–0.25 Ma) of human prehistory and charts a technological progression from simple Old-owan stone chips to large, skilfully shaped Acheulean cutting tools. During this period hominin brain size nearly tripled, from the high end of the chimpanzee range to the low end of the modern human range. It is reasonable to conjecture that many distinctive aspects of modern human brain structure and function evolved during this period of massive brain expansion. More controversial is the role which changing lithic technologies may have played as cause, consequence or correlate to hominin brain and cognitive evolution (e.g. Ambrose

2001; Deacon 1997; Gibson & Ingold 1993; Mithen 1996; Noble & Davidson 1996; Roux & Bril 2005; Wynn 2002; Wynn & McGrew 1989).

Of particular interest have been possible relations between language, gesture and tool-use in human evolution. Such relations have received renewed attention in recent years as a result of research into motor resonance, the tendency for neural structures involved in action execution also to be recruited during action observation. Resonance is thought to provide a direct mechanism for understanding the intentions and goals of others through what amounts to a kind of motor 'empathy'. Mirror-neurons found in a putative Broca's area homologue (ventral premotor area F5) in monkeys (Rizzolatti & Craighero 2004) provide a specific demonstration of resonance at the cellular level and have inspired recent hypotheses for the evolution of articulate language through intermediate stages of imitation, pantomime and 'protosign' language (Arbib 2005; Rizzolatti & Arbib 1998). Many other such scenarios and mechanisms for the co-evolution of language and tool-making have been proposed over the years.

A number of researchers have argued that language and tool-making share underlying cognitive and neural requirements for hierarchically structured action sequencing (Greenfield 1991; Holloway 1969). This is consistent with broader motor hypotheses of language origins, which derive key language properties from the multi-level motor coordination required

in speech (Lieberman & Whalen 2000; MacNeilage 1998; Studdert-Kennedy & Goldstein 2003) and/or cerebral asymmetries in manual and vocal control (Corballis 2003; MacNeilage *et al.* 1984). Another, less direct, strand of argumentation has been to emphasize the selective pressures for intentional communication arising from collaborative technological activities (Engels 2003; Reynolds 1993) and pedagogy (Greenfield 1998; Stout 2002).

Palaeolithic stone artefacts provide a unique source of behavioural, chronological and contextual evidence that may be used to constrain such evolutionary hypotheses (Wynn 2002). The availability of this evidence is largely due to the durability of stone artefacts; however putative links between stone tools and language are more than just a matter of convenience for archaeologists. The hand and mouth are the two most complex and flexible effectors of the human body and are regulated by neighbouring or even partially overlapping neural circuits. This is particularly notable in the case of object manipulation (Hamzei *et al.* 2003). These cortical circuits include regions of inferior frontal and parieto-temporal association cortex connected by the arcuate fasciculus (Fig. 1), all of which have been disproportionately expanded (Rilling 2006; Rilling *et al.* 2008) in the massive cortical growth that began soon after the appearance of the first stone tools.

Bipedal locomotion, another distinctive human characteristic, has been hypothetically linked to the evolution of basal ganglia circuits important to language (Lieberman 2002) but does not appear to overlap with cortical language circuits (Santi *et al.* 2003). Furthermore, bipedalism predates significant brain expansion by at least 1.5 million years, was associated with an ape-like vocal tract including laryngeal air-sacs (Alemseged *et al.* 2006), and shows little of the higher-level intentional organization seen in both language and tool-making. Even if bipedalism did promote early preadaptations for speech, it is unlikely to be directly relevant to major subsequent developments. Other putative hominin behaviours such as hunting or social strategizing are complex and cognitively demanding, but do not share demands for the rapid sequencing of complex motor gestures seen in language and tool-making. Lithic and other less archaeologically visible technologies (e.g. Mazza *et al.* 2006; Thieme 1997) involving manual object manipulation thus continue to provide the closest correspondence with language, and are the most likely candidates for hypothetical co-evolutionary relationships.

Until recently, however, empirical evidence of the specific neural and cognitive substrates of particular

ancient technologies has been lacking. In an attempt to address this problem, we have recently undertaken a series of functional brain imaging investigations of ESA tool-making (Stout & Chaminade 2007; Stout *et al.* 2000; 2008). By comparing tool-making with a baseline manipulative task we sought to isolate the distinctive neural demands of ESA technologies. Among other things, this provided evidence of specific points of overlap with cortical language circuits. Here we present a more extended discussion of the theoretical and evolutionary implications of these findings.

Neurobehavioural foundations of articulate language and manual action

Quite some time ago, Holloway (1969) pointed out that any motor act can be described as a hierarchically structured sequence of behavioural 'units'. For Holloway, the more interesting question was whether there is any meaningful correspondence between specific 'units' of speech and stone tool-making. Or, as Arbib (2006) more recently asked, 'a sentence is to speech as what is to action?'. Functional brain imaging results suggest that meaningful correspondences do exist between language and ESA tool-making, and furthermore that these correspondences are to be found at increasingly higher levels of organization in more sophisticated stone technologies.

Articulate language involves the combination of units on at least three nested levels, loosely described as sound combinations (phonology), word combinations (syntax), and conceptual combinations (semantics). Those of an anthropological bent might wish to distinguish a fourth level of more extended conceptual combinations in discourse semantics (Rose 2006). These levels correspond to intervals on increasing scales of temporal duration and hierarchical abstraction.

Patterns of brain activation associated with particular linguistic tasks similarly vary according to scale. This probably reflects general organizational properties of the cerebral cortex (Deacon 1997; Fuster 2001) rather than anything special to language. For example, cortical fields with relatively direct connections to the rest of the body (e.g. primary and secondary sensorimotor areas) generally tend to be involved in rapid processing whereas those increasingly dominated by intracortical connections (association areas) are involved in larger-scale integration across time. There is also good evidence of hemispheric differences in the scale of processing, with the left hemisphere (LH) apparently specializing in small-scale rapid processing and the right hemisphere (RH) specializing in larger scale and

longer duration processing (Deacon 1997). This trend is evident across linguistic (Bookheimer 2002; Poeppel 2003), perceptual (Gazzaniga 2000), and cognitive (Gazzaniga 2000; Goel *et al.* 2007) domains.

The neural bases of manual action reflect many of these same scale-related organizing principles, as well as some points of more specific overlap with systems involved in articulated language. This is particularly evident in inferior lateral frontal cortex, which displays a clear posterior to anterior gradient of increasing processing scale and abstraction (Fiebach & Schubotz 2006; Hagoort 2005; Koechlin & Jubault 2006). This region includes (from back to front) orofacial and manual motor cortex, ventral premotor cortex, and distinct posterior and anterior portions of Broca's area (Fig. 1). All of these appear to play an important role in both articulate language and manual action.

Ventral premotor cortex: phonology and prehension

Many hypotheses of language origins have emphasized the importance of enhanced human articulatory control (e.g. Deacon 1997; Liberman & Whalen 2000; Liberman 2002; MacNeilage 1995; Studdert-Kennedy & Goldstein 2003). This control would appear to arise from increased cortical regulation of the vocal apparatus, and particularly from the contributions of a left hemisphere circuit linking the superior temporal gyrus (Hickok *et al.* 2000) with portions of frontal lobe ventral premotor cortex (PMv) and the adjoining orofacial motor cortex. PMv likely plays an important role in phonological processing (Bookheimer 2002; Hagoort 2005) by combining phonological elements from the superior temporal gyrus into intonational phases.

PMv is thought to play a closely analogous role in the combination of manual grasp elements (e.g. flexion, rotation) provided by parietal lobe association cortex during object prehension (Fagg & Arbib 1998). In fact, PMv participates in multiple neural circuits supporting sensorimotor transformations for action across a variety of modalities. Macaque PMv, for example, displays overlapping responsiveness to visual, tactile and auditory stimuli (Graziano *et al.* 1999), and has recently been found to co-activate with temporal lobe auditory cortex (specifically a putative Wernicke's area homologue) in the perception of species-specific calls (Gil-da-Costa *et al.* 2006). In humans, PMv is divided into inferior and superior fields which are responsive to auditory and visual stimuli respectively (Schubotz & von Cramon 2003). This division, which mirrors the superior/inferior organization of hand and orofacial regions in adjacent

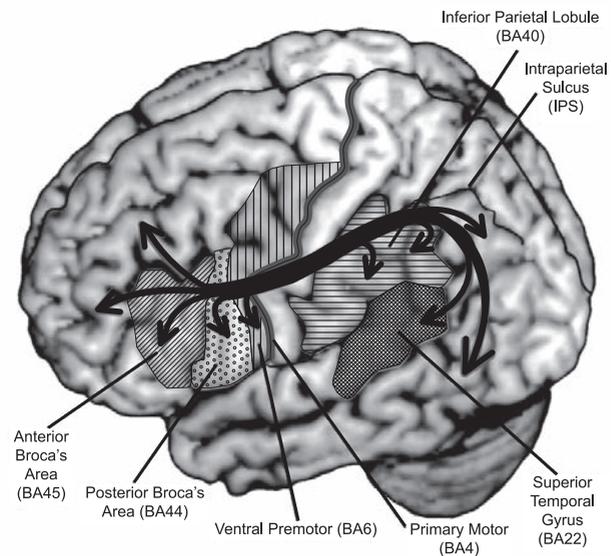

Figure 1. Regions (Brodmann Areas) of frontal, parietal and temporal cortex discussed in the text. Superimposed is the connectivity between frontal and posterior areas via the arcuate fasciculus. (After Rilling *et al.* 2008.)

primary motor cortex, is also evident during action observation, with the superior PMv field responding to observed hand actions and the inferior portion to observed mouth actions (Buccino *et al.* 2001). Kinematic studies reveal that grasping movements with the hand affect concurrent movements of the mouth, with larger manual target objects being associated with wider, faster opening of the mouth and with increased power of the voice spectrum during syllable pronunciation (Gentilucci *et al.* 2001). PMv has thus been characterized as producing an 'action vocabulary' across a wide array of different behaviours, reflecting a more general role in processing sequentially structured events (Schubotz & von Cramon 2004).

PMv activity has been described as characteristically goal-oriented (Rizzolatti *et al.* 1988; Schubotz & von Cramon 2004; van Schie *et al.* 2006). PMv neurons are 'tuned' to specific goals like grasping, placing or holding an object and are less responsive to either discrete action elements (e.g. finger flexion) or larger action composites (e.g. eating a peanut). Individual PMv neurons also display a temporal tuning to particular portions of these goal-directed actions, such as hand opening or closure. These response characteristics indicate the role of PMv in combining discrete gestural elements into simple goal directed actions, much as syllables are produced from coordinated patterns of articulatory 'gestures' by the tongue, lips, velum and so forth (Studdert-Kennedy & Goldstein 2003).

Overlapping PMv contributions to phonological processing and object manipulation provide evidence of a specific neurobehavioural correspondence between language and manual action involving this region. In particular, this correspondence is found at the level where discrete articulatory and prehensile elements are assembled into short goal directed action units, such as grasping an object or pronouncing an intonational phrase.

Posterior Broca's area: syntax and action sequencing

Anterior to PMv in inferior prefrontal cortex is Broca's area, classically associated with fluent speech production. A more current view sees Broca's area as multifunctional, involved in both linguistic and non-linguistic behaviours, and encompassing a posterior-anterior gradient from phonology to syntax to semantics (Hagoort 2005). The more posterior portion of Broca's area (Brodmann Area [BA] 44) is preferentially recruited during syntactical processing (Bookheimer 2002) and appears to support the combination of lexical elements at the sentence level. Loosely, this level of syntactical organization reflects aspects of word order and phrase structure that may or may not affect meaning, as in 'The woman lit the match that started the fire' vs 'The match that the woman lit started the fire.'

Posterior Broca's area is also active during the observation and execution of object-directed actions (Hamzei *et al.* 2003), and is specifically involved in the processing of simple action chunks. Koechlin & Jubault (2006) were able to characterize this functional contribution of Broca's area using a hierarchically structured sequential button pressing task. This task included 'simple chunks' consisting of pre-learned button press sequences as well as 'superordinate chunks' in which the *rules* governing button selection changed according to a pre-learned sequence. Results showed a clear posterior-anterior gradient, with PMv active between single acts, posterior Broca's area active during transitions between simple chunks, and anterior Broca's area active between superordinate chunks. This led Koechlin & Jubault (2006, 968) to conclude that 'posterior [Broca's area] regions are involved in selecting and inhibiting simple action chunks in response to external signals or as successive components of ongoing superordinate actions'. Applied to lexical elements, this would also be a reasonable description of the role of posterior Broca's area in language processing, suggesting a further correspondence between language and manual action at the level of syntax and action sequencing.

Anterior Broca's area: semantics and meaningful action

Anterior Broca's area (here including BA 45 and 47) is involved in semantic unification (Hagoort *et al.* 2004). An example of such unification is the clarification of ambiguous word meanings in relation to broader world knowledge and sentence context. This requires increased hierarchical abstraction of the kind attributed to anterior Broca's area by Koechlin & Jubault (2006) as well as the ability to integrate information over a relatively extended temporal frame. Both characteristics fit well with the general trend toward more abstract, integrative, longer-duration and modality-independent processing in more anterior prefrontal cortex (Deacon 1997; Petrides 2005). The selective involvement of anterior Broca's area in the semantic processing of words and sentences is well attested in the neuroimaging literature (Bookheimer 2002; Martin & Chao 2001), and likely reflects an underlying role in the retrieval and selection between semantic representations (Kan *et al.* 2006; Martin 2003).

Anterior Broca's area is similarly involved in non-linguistic action semantics. For example, the more caudal portion (BA 45) is preferentially recruited during the observation of meaningful actions (like opening a bottle or hammering a nail) as opposed to meaningless hand motions (Decety *et al.* 1997). The more rostral BA 47 has been implicated in numerous higher-order aspects of action organization, including task switching, reversal learning and the selection, comparison and evaluation of stimuli held in memory (Ramnani & Owen 2004), which are critical to the production of complex, flexible and goal-oriented behaviours. This indicates a third correspondence between language and manual action at the level of semantics and meaningful action.

Right cerebral hemisphere: discourse and complex, multi-step action

Further increases in temporal scale to the level of discourse are associated with increased involvement of the right cerebral hemisphere. Although the left hemisphere (LH) has classically been viewed as the 'language hemisphere' it is now clear that this is an oversimplification. In fact, both hemispheres are commonly activated in speech perception (Poeppel 2003), and the right hemisphere (RH) is known to play an important role in larger-scale elements of language, including metaphor, figurative language, connotative meaning, prosody, and discourse comprehension (Bookheimer 2002; Xu *et al.* 2005).

Bilateral activation is also present in Broca's area and its RH homologue during hierarchically structured manual action (Koechlin & Jubault 2006).

Although there is strong evidence of a left-lateralized system involved in planning single actions with everyday tools (Johnson-Frey *et al.* 2005), the actual use of tools tends to produce a less pronounced LH dominance (Lewis 2006). When it comes to assembling more protracted action sequences, RH plays a key role. For example, Frey & Gerry (2006) found that RH and not LH activation was correlated with success in imitating the specific sequence of actions used in assembling a tinkertoy. Hartmann and colleagues (2005) similarly found that, although patients suffering RH brain damage are typically unimpaired in the single-action use of familiar tools, they are impaired when it comes to executing multi-step, naturalistic actions like making a cup of coffee. This suggests a final correspondence between language and manual action at the level of pragmatic discourse and complex, multi-step action.

Making sense: meaning in language and tool-making

The preceding survey highlights the facts that (1) language is not a single 'thing' but rather a complex phenomenon involving multiple interacting systems and levels of organization, and (2) the particular neural substrates of language reflect more general trends of brain organization and overlap extensively with other forms of intentional action. This is consistent with the view that language is a complex learned behaviour mapped onto relevant brain systems, rather than the product of invariant, genetically specified 'language circuits' (Deacon 1997). Similarities in the hierarchical processing requirements of language and manual action result in neural overlap on a variety of levels.

The particular points of overlap described above support and refine the early work of Holloway (1969) who proposed that stone tool-making, like language, involves 'phonemic', 'grammatical' and 'semantic' levels of organization. Holloway suggested that the phonemic level might include actions like striking a flake or rotating the core, that the grammar is a concatenation of these elements, and that the semantics are to be found in the intended purpose of individual actions and finished tools. The more recent evidence discussed above suggests that the 'phonemic' units should probably be smaller (e.g. hand configurations, arm movements) than those envisioned by Holloway, with relatively straight-forward knock-on effects on the scale of the rest of the scheme. One key point that does require further consideration, however, is the concept of tool-making 'semantics'.

The issue of meaning is central to Holloway's broader argument about the uniqueness of human culture, which he identifies with 'the imposition of

arbitrary form on the environment'. Ingold (1996) has similarly argued that human uniqueness resides in 'the self-conscious authorship of design' and the projection of symbolic meaning onto the environment. Symbolic meaning is obviously a key feature of human language and culture, but in what sense might it be evident in stone tool-making?

As Deacon (1997; 2003) has explained, symbolic reference is itself constructed in a hierarchical fashion from underlying iconic and indexical relationships. Iconicity, rooted in physical similarity, is the basis for recognizing different instances of a behaviour (e.g. vocal utterances, hand postures) as the same 'thing'. Indexicality is then based on correlation (causal *or* arbitrary) between iconically related classes of stimuli, for example smoke and fire, food and a bell, or the word 'apple' and an apple. Symbolic reference lies on the next level of the hierarchy as a relationship between indices. More precisely, the referential power of a symbol comes from 'its position within a structured set of indexical relationships among symbol tokens' (Deacon 2003, 122). For example, the symbolic meaning of 'apple' comes from a superordinate system of indexical associations with other words like 'fruit', 'sweet' or 'computer' as well as from immediate context. This is why dictionaries define word meaning by providing systematic mappings of each word onto others.

In stone tool-making, one might similarly say that the meaning of an action comes from its possible associations with other actions in a superordinate system of technological rules. The closest correspondence with word meaning is probably at the level of relations between individual goal-oriented actions, as in striking a flake as part of a planned reduction sequence. The meaning of this action is constructed by recognizing iconic stimulus classes (grips, gestures, outcomes), their indexical (cause and effect) relation to each other, and finally the possible relationship of these indexical relationships to each other in achieving a technological goal. The hierarchical structure involved is thus formally similar to that used in constructing symbolic reference. But is meaning in the sense of the goal-oriented intention of an action really comparable to symbolic meaning? This depends on what it actually means for a tool-making act to be 'intentional'.

'Intentional' is a word used in multiple ways. In everyday speech it typically means 'deliberate' or 'on purpose'. For philosophers it has come to have a more specialized meaning, denoting 'aboutness' (Dennett & Haugeland 1987) or the property of referring to or being directed at something (the 'intentional object'). In both colloquial and technical senses 'intention' is about

meaning, be it the meaning of an action (Did you intend to do that?) or the meaning of a symbol (Do you mean 'an apple', 'the apple of my eye', or 'Apple Computers'?). In each case meaning is dependant on context and exists on multiple levels (Searle 1992). For example, a stone tool-maker might simultaneously intend to move his arm, to detach a flake, to modify a bifacial edge, to shape a handaxe, to disarticulate a carcass, and to increase his prestige through a display of skill, depending on the level of description (Keijzer 1998; Stout 2002). Similarly, it is part of the power of language that 'I hear you' can be a statement of fact, an indication of agreement, and a gesture of support, all at the same time. The true 'meaning' of this statement has to do with the level of discourse to which one attends.

This highlights the fact that speech is itself a form of action (Austin 1975) used to enact relations and construe experience (Rose 2006). Internal cogitation, often including sub-vocal speech, is also typically aimed at construing experience in one way or another. Even such apparently abstract intentional phenomena as hopes and beliefs may be seen as concrete *reactions* to the world, with meanings defined in relation to our goals (e.g. seeking gratification, understanding our surroundings). On this view, intentionality is a property of goal-directed interactions between agent and environment. From this it follows that the 'level' at which we find intentionality is closely related to the behavioural competence of the agent:

Thus, for example, the beginning skier may require an intention to put the weight on the downhill ski, an intermediate skier has the skill that enables him to have the intention to 'turn left,' a really expert skier may simply have the intention to 'ski this slope'...Similarly, when I am speaking English, I do not have the intention to match singular nouns with singular verbs or plural nouns with plural verbs — I just talk. (Searle 1992, 195)

Depending on the social and linguistic aptitude of the speaker, 'just talking' might similarly contribute to a range of higher-order intentions. For example, the exaggerated intonational contours and repetition typical of infant directed speech ('motherese') may serve to facilitate word segmentation and phoneme recognition during language acquisition (Falk 2004). Similarly, in stone tool-making the intentional exaggeration of certain actions for the benefit of observers might serve a pedagogical purpose. Together with other forms of intentional instruction and collaborative technological action, such demonstration would provide a context for the transition from imitation to intentional communication without the need for an intermediate 'protosign' stage (*contra* Arbib 2005).

Early Stone Age tool-making and language evolution

ESA knapping methods include Mode I (Clark 1961) flake production and Mode II bifacial shaping. Mode I flaking is characteristic of the Oldowan Industrial Complex (Isaac 1976), which is currently known from 2.6–c. 1.5 Ma (although examples of this simplest of knapping methods may be found throughout prehistory). The method involves the production of sharp-edged flakes by striking one stone (the core) with another (the hammerstone). Mode II knapping, which requires the deliberate shaping of the core to achieve a pre-determined form, first appears after c. 1.7 Ma and characterizes the Acheulean Industrial Complex (Clark 1994). The prototypical Acheulean artefact is the so-called 'handaxe', a more-or-less symmetrical, teardrop-shaped tool systematically worked on both faces and well-suited for butchery and other heavy-duty cutting tasks (Schick & Toth 1993). The archaeologically documented progression from Mode I to Mode II tool-making provides direct evidence of increasing hierarchical complexity in at least one sphere of early hominin behaviour, as well as indirect evidence of increasingly effective mechanisms for the social reproduction of technological skills.

Mode I tool-making and PMv expansion

Effective Mode I flake detachment requires visuomotor coordination and evaluation of three-dimensional core morphology (Stout & Chaminade 2007) so that forceful blows may reliably be directed to appropriate targets. In addition to sophisticated visual perception, this requires speed and accuracy (Stout 2002) of the right¹ hand in delivering blows and the use of effective grips (Marzke *et al.* 1998) by both hands so that the stones may be properly stabilized and oriented with points of impact exposed. Detailed evidence of the complex and demanding motor synergies of the right limb involved in effective percussion comes from experimental studies of traditional stone bead knappers in India (Biryukova *et al.* 2005; Roux *et al.* 1995). Modern knappers engaged in freehand percussion (the most likely posture for Oldowan knapping) further report that the fingertips of the left hand, positioned directly below the point of impact, can serve as a proprioceptive guide to percussion (Stout 2002) and exert pressure that may help to guide flake detachment (Jones 1994).

Brain activation during Mode I knapping (Stout & Chaminade 2007; Stout *et al.* 2008) reflects these visuomotor challenges, including visual shape perception and manual grip coordination. Of particular interest is activation of an object prehension circuit

linking the anterior intraparietal sulcus (IPS) and ventral premotor cortex (PMv). As described above, this circuit is thought to support the combination of grasp elements into an 'action vocabulary', much as a parallel circuit connecting superior temporal gyrus to PMv is thought to support the combination of phonological elements into intonational phases.

This is broadly consistent with the evolutionary-developmental hypothesis of Greenfield (1991), who proposed that discrete manual and linguistic circuits in the posterior inferior frontal lobe emerge through postnatal developmental differentiation of a common neural substrate. Such differentiation is thought to result from the exuberant growth and subsequent pruning of synaptic connections, driven by neuronal competition, intrinsic gene expression gradients, and extrinsic stimuli. This is a plastic process, even into adulthood (Hihara *et al.* 2006), and it is quite plausible that PMv expansion related to selection for manipulative functions could have provided an exaptive foundation for the evolution of neighbouring articulatory circuits.

Evidence of preferential PMv recruitment during Mode I tool-making by modern humans (Stout & Chaminade 2007; Stout *et al.* 2008) strongly suggests that comparable tool-making by Oldowan hominins also involved similarly distinctive demands on the primitive (Rizzolatti *et al.* 1998) manipulative functions of this region. Expansion of PMv would be one possible outcome of selection acting on these functions and, in fact, premotor cortex as a whole does seem to be expanded in humans (Blinkov & Glezer 1968), though not to the same extent as prefrontal and temporo-parietal association cortices (Deacon 1997; Rilling 2006). The appearance of Oldowan tools 2.6 million years ago provides evidence of novel demands and capabilities for action organization in this region, and may have contributed to the evolution of the neural substrates of articulate language. This scenario differs from Greenfield's (1991) proposal in that it deals with articulatory and manual coordination in PMv rather than word and object combination in Broca's area, and by virtue of its specific link to the archaeological record. However the proposals are not mutually exclusive and the underlying evolutionary logic is the same.

Mode II tool-making and anterior Broca's area

Although initially quite crude, by the later ESA (< 0.5 million years ago) many handaxes achieved a level of refinement indicative of advanced tool-making skills (Edwards 2001) and possibly of aesthetic concerns beyond the purely utilitarian (Machin *et al.* 2007). In comparison to Mode I tool-making, the production of such tools involves increased demands for hierarchical

action organization and fine bimanual coordination. In the brain, this is associated with additional activation of the RH homolog of anterior Broca's area (Stout *et al.* 2008).

As described elsewhere (Stout *et al.* 2006; 2008), the additional demands of Mode II tool-making have a lot to do with the need to strike highly invasive 'thinning flakes' that travel at least half way across the surface of the piece. This is accomplished through careful platform preparation, often using a different hammerstone and following very different technical rules from primary flake detachment. Various different percussors and techniques may also be used to accomplish sub-goals such as bifacial edging, thinning and shaping. The production of a well-formed handaxe thus requires individual actions to be coordinated, not only with respect to the ultimate goal, but also in terms of various superordinate rule systems pertaining to different technical operations. This is analogous to the superordinate sequencing task of Koehlin & Jubault (2006), which also elicited (bilateral) anterior Broca's area activation. The activation of the RH Broca's homologue specifically by Mode II tool-making likely reflects the particularly critical role of the left hand in manipulating, orienting and supporting the core (Stout *et al.* 2008), and may also have to do with putative specializations of this region for response inhibition and task-set switching (Aron *et al.* 2004).

Anterior Broca's area and RH contributions to higher-level aspects of language and multi-step action organization are described above. Activation of this region during Mode II tool-making by modern humans (Stout *et al.* 2008) provides direct evidence of the increased hierarchical complexity of the activity, and implies similar demands in comparable prehistoric (i.e. late Acheulean) technologies. While handaxe making does not provide direct evidence of language capacities, it does reflect the presence of hierarchical processing capabilities important to both activities. These may have been in place at an earlier date, but are first attested in the archaeological record by the appearance and subsequent refinement of Mode II tool-making. As was the case with PMv and Mode I tool-making, this neurobehavioural overlap is also consistent with the hypothetical co-evolution of linguistic and tool-making capabilities.

Conclusion

It is nothing new to propose an evolutionary link between language and tool-making. In 1871, Darwin (2004, 69) himself argued that 'To chip a flint into the

rudest tool...demands the use of a perfect hand...the structure of the hand in this respect may be compared with that of the vocal organs'. In more recent years, however, many archaeologists have instead stressed the *dissimilarities* between language and stone tool-making (e.g. Chase 1991; Graves 1994; Mithen 1996; Noble & Davidson 1996; Wynn 1995). Brain-imaging studies of ESA tool-making (Stout & Chaminade 2007; Stout *et al.* 2008) provide important new empirical support for the early intuitions of Darwin, as well as for more recent proposals regarding the co-evolution of language and technology.

The unique contribution of the imaging studies is to establish direct links between archaeologically visible behaviours and neural substrates. Results to date highlight the demands of manual grasp coordination in PMv during both Mode I and Mode II tool-making and the increased prefrontal (anterior Broca's area) and RH demands of Mode II tool-making. The increasing sophistication of ESA tool-making seen through time thus documents the expression to increasingly complex capacities for hierarchical action organization. Furthermore, this progression closely parallels ascending phonetic, syntactical, semantic and discourse levels of language processing in terms of both formal structure and neural organization. While stone tools still do not provide direct evidence of linguistic abilities, they do indicate the presence of analogous capacities in the realm of manual action organization (Holloway 1969). This is consistent with the hypothesis that selection acting on tool-making ability could have contributed to the evolution of language-relevant neural circuits (and *vice versa*) through a process of developmental displacement (Greenfield 1991).

Other recent hypotheses of language origins have focused on three key features: parity, recursion and symbolic reference. Parity is the requirement that sender and receiver attribute the same meaning to same elements of communicative behaviour. In other words, an iconic relationship must be established between actions which are the 'same' whether produced by the self or perceived in another. In the realm of manual action this is thought to be achieved through the phenomenon of motor resonance, in which the same neural substrates are recruited during action observation as during action execution. Such resonant properties are evident in human premotor cortex, including but not limited to Broca's area. Mirror neurons found in the ventral premotor cortex (area F5) of monkeys offer one specific example of resonance and, although homologous neurons have not been observed in humans, have inspired hypothetical scenarios of language evolution in which manual

imitation led to 'protosign' language and eventually protospeech (Arbib 2005; Rizzolatti & Arbib 1998).

Preferential recruitment of PMv and the RH homolog of Broca's area during stone tool-making directly grounds such hypotheses in the known activities of early hominins. The close correspondence in the multi-level intentional structure of tool-making and articulate language may even obviate the need for a transitional protosign stage, which has previously been proposed as a necessary bridge between imitation and intentional communication (Arbib 2005). Technological pedagogy and joint action provide equally plausible, archaeologically attested contexts for this transition without the need to posit an intermediate evolutionary stage with no modern analogue. A similar proposal was actually made by Friedrich Engels 125 years ago: 'the development of labour necessarily helped to bring the members of society closer together by increasing cases of mutual support and joint activity, and by making clear the advantage of joint activity to each individual. In short, men in the making arrived at the point where they had something to say to each other' (2003, 73).

Parity may be a basic requirement for any communicative system, but it does not explain the great complexity and power of human language. This power is often attributed to the property of recursion or 'discrete infinity' which allows discrete units to be combined and re-combined in a (theoretically) infinite series of nested layers. Recursion has been singled out by some as *the* core element of language unique to humans (Hauser *et al.* 2002), but it is not clear that linguistic recursion is really so different from the hierarchy of behavioural chunks seen in stone tool-making or any other motor behaviour (Holloway 1969). What appears important is the level of abstraction at which recursion is employed. Linguistic recursion is theoretically infinite, but in practice the use of more than a few embedded phrases tends to be very confusing for the listener. Similarly, one might imagine an arbitrarily complex series of nested operations in tool-making, although this does not occur in practice. Indeed, the observed neural overlap between Mode II tool-making and semantic language processing suggests that the degree of recursion involved may not be that different, at least in terms of how it is handled by the brain.

Much the same may be said of the relation of stone tool-making to symbolic reference. In both cases meaning is constructed in a hierarchical fashion from iconic and indexical relationships. The real question is whether the specific units of construction are in any way comparable. It has been argued that comparisons between symbolic reference and tool-making are

misleading (Chase 1991; Graves 1994; Noble & Davidson 1996; Wynn 1995), however the brain imaging evidence suggests that important overlap does exist. In the end, we may come to see language and tool-making as alternate expressions of an underlying human capacity to make sense of the world in increasingly complex ways.

Notes

1. For simplicity, and because all subjects in the experiments discussed here were right-handed, 'right hand' and 'left hemisphere' will be used to refer to the 'dominant' side. This also avoids some misleading terminology, in that hands and hemispheres are best seen as specialized for different tasks rather than simply being 'dominant' or 'non-dominant'.

Author biographies

Dietrich Stout is a Lecturer in the Archaeology of Human Evolution at the University College London, Institute of Archaeology. His research has included ethnographic observations of stone tool-making in highland New Guinea, archaeological fieldwork at the site of Gona in Ethiopia, and experimental investigations of stone tool-making action organization and brain activation.

Thierry Chaminade is a CNRS research scientist at the Mediterranean Institute for Cognitive Neuroscience. He obtained his PhD in Cognitive Neuropsychology in 2003 for his contribution to the understanding of the neural mechanisms of human imitation. He continues to work on the overlap between action execution and perception, addressing scientific questions ranging from human evolution to humanoid robotics.
